A comparison of escape rates from one and from two holes in an experimental container (e.g. a laser trap) can be used to obtain information about the dynamics inside the container. If this dynamics is simple enough one can hope to obtain exact formulas. Here we obtain exact formulas for escape from a circular billiard with one and with two holes. The corresponding quantities are expressed as sums over zeroes of the Riemann zeta function. Thus we demonstrate a direct connection between recent experiments and a major unsolved problem in mathematics, the Riemann hypothesis.

Billiard systems, in which a point particle moves freely except for specular reflections from rigid walls, permit close connections between rigorous mathematics and experimental physics. Very general physical situations, in which particles or waves are confined to cavities or other homogeneous regions, are related to well understood billiard dynamical systems, directly for particles and via semiclassical (short wavelength) theories for waves. Precise billiard experiments have used microwaves in metal [1, 2] and superconducting [3] cavities and with wave guides [4], visible light reflected from mirrors [5], phonons in quartz blocks [6], electrons in semiconductors confined by electric potentials [7, 8], and atoms interacting with laser beams [9, 10, 11]. Experiments employ both two and three [12] dimensional geometries, and both closed and open systems. For instance, escape of cold atoms from a laser trap with a hole was studied in [9, 10]. Closed systems exhibit energy level distributions and scarring of wavefunctions as predicted by semiclassical [13] and random matrix [14] theories. Open systems exhibit unexpected and incompletely understood phenomena such as fractal conductance fluctuations [8, 15, 16, 17]. For both closed and open systems, the behavior depends crucially on the classical dynamics, which can be tuned to be integrable, chaotic, or mixed [9, 10, 15, 18]. Escape rate is a characteristic of open billiards which is both experimentally accessible [9, 10] and important for transport properties of many systems. In this paper we propose to ask what may be understood about the intrinsic dynamics of billiards using only this experimental escape information, specifically by comparing systems with one and two holes. The two hole escape rate is not measured in the experimental literature, but presents no fundamental difficulties. We naturally begin with the simplest of shapes, the circle, and find remarkable exact expressions based on the most famous unsolved mathematical problem, the Riemann Hypothesis.

At long times, the probability of a particle remaining in an integrable billiard with a hole is well known to exhibit power law decay, in contrast to exponential decay from strongly chaotic billiards [19], however the coefficient of the power ("escape rate") in the integrable case has not been computed exactly to our knowledge. Numerical simulations can lead not only to uncertainty in the coefficient, but also misleading conclusions, for example the power law decay of an integrable billiard can be masked by an exponential term at short times.

Here we consider the circle billiard, which is integrable due to angular momentum conservation. Some three dimensional cases, namely the cylinder and sphere, can be treated analogously. The circle billiard of unit radius has collisions defined by the angle around the circumference  $\beta \in (-\pi,\pi]$  and the angle between the outward trajectory and the normal  $\psi \in (-\pi/2,\pi/2)$ . The billiard map is then  $(\beta,\psi) \to (\beta+\pi-2\psi,\psi)$  where angles are taken modulo  $2\pi$  as usual. The time between collisions is  $T=2\cos\psi$ .

The dynamical evolution is of two types depending on the value of  $\psi$ . For  $\psi = \psi_{m,n} \equiv \pi/2 - m\pi/n$  with m < n coprime integers, the trajectory is periodic with period n and the  $\beta$  values are equally spaced at intervals of  $2\pi/n$ . For  $\psi$  which are irrational multiples of  $\pi$ , the trajectory is uniformly distributed in  $\beta$  (see for example Prop. 4.2.1 of Ref. [20]).

For the escape problem the billiard is filled with a uniform density of particles normalised to unity given by  $\cos\psi d\beta d\psi/(4\pi)$  at the boundary; this is the usual equilibrium measure for two dimensional billiards. Note that for the circle, any function of  $\psi$  leads to an invariant measure since  $\psi$  is a constant of motion. Two (possibly overlapping) holes are placed at the boundary at  $\beta \in [0, \epsilon]$  and  $\beta \in [\theta, \theta + \epsilon]$ ; the one hole problem is simply  $\theta = 0$ . The number of collisions to escape is some function  $N(\beta_0, \psi_0)$  (possibly infinite) of the initial conditions and the time to escape is  $t = NT = 2\cos\psi N(\beta_0, \psi_0)$ . Considering

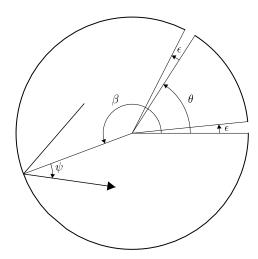

FIG. 1: Geometry of the billiard.

the continuous and discrete time problems leads to escape times differing at most by the maximal free path of 2; only the discrete time calculation will be required for the leading (in time) behavior of escape, that is, the coefficient of 1/t for the density remaining at time t. The geometry of the billiard is shown in Fig. 1.

From above, the only trajectories which do not escape are some of the periodic orbits with period  $n < 2\pi/\epsilon$ . For an arbitrary aperiodic (finite time) orbit we define the period n to be the smallest positive integer for which  $|\phi_n - \phi_0| \le \epsilon$ . For the largest possible value of  $n < 2\pi/\epsilon$ , the n+1 points  $\phi_0, \phi_1, \ldots \phi_n$  automatically have a minimum distance  $\le \epsilon$  on the circle, so the inequality is satisfied by this definition. In units of n collisions, the particle's orbit precesses slowly enough to be captured by one of the holes, so at very large values of t, only slightly precessing orbits remain.

Now we compute the density remaining near periodic orbits  $(\beta_0, m, n)$  at long time t. Such a long lived trajectory has  $\psi = \psi_{m,n} + \eta$  for  $\eta \ll \epsilon$ . A prime will indicate values taken modulo  $2\pi/n$  and lying in  $[0, 2\pi/n)$ . Thus the dynamics is now  $\beta' \to \beta' - 2\eta$  and escape takes place when this passes one of the values  $\epsilon$  or  $\epsilon + \theta'$  for  $\eta > 0$ , or 0 or  $\theta'$  for  $\eta < 0$ . The set of initial conditions for which escape takes at least time t, hence  $t/(2\cos\psi_{m,n})$  collisions is thus

$$\beta_0' \in \left(\epsilon + \frac{\eta t}{\cos \psi_{m,n}}, \theta'\right) \bigcup \left(\theta' + \epsilon + \frac{\eta t}{\cos \psi_{m,n}}, \frac{2\pi}{n}\right)$$
(1)

for  $\eta > 0$  and similar expressions for  $\eta < 0$ . Integrating over this region, including the  $\cos \psi$  weighting for the invariant measure and a factor n to account for the equivalence modulo  $2\pi/n$ , and summing over all non-escaping periodic orbits gives

$$P(t) \sim \frac{1}{4\pi} \sum_{m,n} \frac{n \left[ g \left( \frac{2\pi}{n} - \theta' - \epsilon \right) + g \left( \theta' - \epsilon \right) \right]}{t} \sin^2 \frac{\pi m}{n}$$

$$g(x) = \begin{cases} x^2 & x > 0 \\ 0 & x \le 0 \end{cases} \tag{2}$$

where the sum is restricted to  $0 \le m < n < 2\pi/\epsilon$  for coprime m, n, and faster decaying terms in t have been neglected (for example in approximating  $\cos \psi$  by a constant near each periodic orbit). Note that n=1 is included, but gives no contribution. Now we write the sin functions as sums of exponentials and apply the Ramanujan identity [21]

$$\sum_{\substack{m=0\\\gcd(m,n)=1}}^{n-1} e^{2\pi i m/n} = \mu(n)$$
 (3)

where  $\mu$  is the Möbius function, defined by  $\mu(1) = 1$ ,  $\mu(p) = -1$  for primes p,  $\mu(mn) = \mu(m)\mu(n)$  if gcd(m,n) = 1, otherwise  $\mu(mn) = 0$ . The result is

$$P_{\infty} \equiv \lim_{t \to \infty} t P(t) = \frac{1}{8\pi} \sum_{n=1}^{\infty} n(\phi(n) - \mu(n))$$
$$\times \left[ g\left(\frac{2\pi}{n} - \theta' - \epsilon\right) + g\left(\theta' - \epsilon\right) \right] \tag{4}$$

Here  $\phi(n)$  is the Euler totient function, giving the number of positive integers  $m \leq n$  with  $\gcd(m,n) = 1$ . Conventionally  $\phi(1) = 1$ . Of course  $P_{\infty}$  depends on both  $\epsilon$  and  $\theta$ , but this is suppressed for brevity.

 $P_{\infty}$  is a finite sum, piecewise smooth when considered as a function of  $\epsilon$  and/or  $\theta$  with the number of terms unbounded in the limit of small  $\epsilon$ . For small holes we can extract the asymptotic behavior using Mellin transforms. Write  $\tilde{P}(s) = \int_0^\infty P_{\infty} \epsilon^{s-1} d\epsilon$  and then  $P_{\infty} = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \epsilon^{-s} \tilde{P}(s) ds$  gives the required asymptotic series as a sum of residues. The constant c is determined by convergence of the first integral. This integral is finite  $(P_{\infty} = 0 \text{ when } \epsilon > \pi)$  and so converges for sufficiently large s, leading to a constant c to the right of all poles of  $\tilde{P}(s)$ . For sufficiently large s convergence of the sum is uniform in  $\epsilon$ , so interchanging the sum and the first integral, integrating over  $\epsilon$  and substituting  $\theta' = f(n\theta/(2\pi))2\pi/n$  where f indicates the fractional part, we find

$$P_{\infty} = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \frac{ds e^{-s} (2\pi)^{s+1}}{2s(s+1)(s+2)} \sum_{n=1}^{\infty} \frac{\phi(n) - \mu(n)}{n^{s+1}} \times \left\{ \left[ 1 - f\left(\frac{n\theta}{2\pi}\right) \right]^{s+2} + f\left(\frac{n\theta}{2\pi}\right)^{s+2} \right\}$$
(5)

Now we consider the case of rational angles  $\theta = 2\pi r/q$  where gcd(r,q) = 1; the r = 0, q = 1 case gives a single hole. In this case the sum over n splits into conjugacy classes modulo q and the fractional parts are known rational numbers which depend only on the conjugacy class.

Let us consider the required sum

$$\sum_{n \equiv a \pmod{q}} \frac{\phi(n) - \mu(n)}{n^{s+1}} \tag{6}$$

by first dividing all quantities through by b = gcd(a, q), writing n' = n/b, a' = a/b and q' = q/b. We then have

$$\sum_{n' \equiv a' \pmod{q'}} \frac{\phi(bn') - \mu(bn')}{(bn')^{s+1}} \tag{7}$$

with a' and q' coprime. Now we consider Dirichlet characters [21]  $\chi(n')$ , defined as follows. The conjugacy classes modulo q' which are coprime to q' form an abelian group under multiplication, of order  $\phi(q')$ . Since the group is abelian and finite, there are  $\phi(q')$  irreducible representations  $\chi$  in which each n' coprime to q' is represented by a complex root of unity  $\chi(n')$  satisfying  $\chi(m')\chi(n') = \chi(m'n')$ ;  $\chi(n') = 0$  if n' and q' have a common factor.

A central result in representation theory is the orthogonality theorem, here [21]

$$\frac{1}{\phi(q')} \sum_{\chi} \bar{\chi}(a') \chi(n') = \delta_{a',n'} \tag{8}$$

where  $\delta_{a',n'} = 1$  if  $a' \equiv n' \pmod{q'}$ , zero otherwise, and the bar indicates complex conjugation.

Inserting the orthogonality relation into the sum allows n' to be summed over all integers and decomposed into prime factors  $n' = \prod_n p^{\alpha_p}$ ,

$$\sum_{n \equiv a \pmod{q}} \frac{\phi(n) - \mu(n)}{n^{s+1}}$$

$$= \frac{1}{\phi(q')} \sum_{\chi} \bar{\chi}(a') \sum_{n'=1}^{\infty} \chi(n') \frac{\phi(bn') - \mu(bn')}{(bn')^{s+1}} \qquad (9)$$

$$\chi(n') = \prod_{p} \chi(p)^{\alpha_p}, \quad \phi(bn') = \phi(b) \prod_{p|n', p \nmid b} (1 - p^{-1})$$

$$\mu(bn') = \begin{cases} \mu(b) \prod_{p} (-1)^{\alpha_p} c^2 \not |bn'| & \text{for all } c > 1 \\ 0 & \text{otherwise} \end{cases} \qquad (10)$$

The condition on  $\mu$  is taken into account by setting  $\alpha_p = 0$  if p|b and summing  $\alpha_p = 0, 1$  otherwise. The sum for  $\phi$  is given by the  $\alpha = 0$  term together with a geometric series. The result is

$$\sum_{n \equiv a \pmod{q}} \frac{\phi(n) - \mu(n)}{n^{s+1}}$$

$$= \frac{1}{b^{s+1}\phi(q')} \sum_{\chi} \frac{\bar{\chi}(a')(\phi(b)L(s,\chi) - \mu(b))}{L(s+1,\chi) \prod_{p|b} (1-\chi(p)p^{-s-1})}$$
(11)

where characters are taken modulo q' and

$$L(s,\chi) = \sum_{n=1}^{\infty} \frac{\chi(n)}{n^s} = \prod_{p} (1 - \frac{\chi(p)}{p^s})$$
 (12)

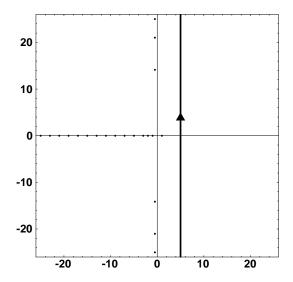

FIG. 2: Poles of  $\tilde{P}(s)$  (Eq. 14) for q=1 (one hole) at -2, odd integers less than or equal to 1, and nontrivial values with real part -1/2 assuming the Riemann hypothesis. The contour of Eq. 5 is given.

is the Dirichlet L function, which in the case q'=1 (ie  $\chi(n)=1$  for all n) reduces to the Riemann zeta function. For each q' there is a trivial character for which  $\chi(a')=1$  for all a' coprime to q'; this gives the same product as the Riemann zeta function, excluding primes dividing q', thus

$$L(s,1) = \zeta(s) \prod_{p|q'} (1 - p^{-s})$$
 (13)

Our first main result is the exact expression for the probability P(t) of remaining in the unit circular billiard with two holes  $[0, \epsilon]$  and  $[2\pi r/q, 2\pi r/q + \epsilon]$  is thus

$$\lim_{t \to \infty} t P(t) = \sum_{j} \operatorname{res}_{s=s_{j}} \tilde{P}(s) \epsilon^{-s}$$

$$\tilde{P}(s) = \frac{(2\pi)^{s+1}}{2s(s+1)(s+2)} \sum_{a=1}^{q} \frac{(1-f(\frac{ap}{q}))^{s+2} + f(\frac{ap}{q})^{s+2}}{b^{s+1}\phi(q')}$$

$$\times \sum_{\chi} \frac{\bar{\chi}(a')(\phi(b)L(s,\chi) - \mu(b))}{L(s+1,\chi) \prod_{p|b} (1-\chi(p)p^{-s-1})}$$
(14)

where, as above, b = gcd(a,q), a' = a/b, q' = q/b and the characters are taken modulo q'. In performing the contour integral (Fig. 2) we recall that the contour lies to the right of all poles of the integrand (c > 1) and that a semicircular arc to the left may be added that avoids the poles and for which the integral vanishes in the limit of infinite radius. For large negative real part the integrand is controlled by the  $(2\pi)^{s+1}$  and for large imaginary part the integrand is controlled by the cubic prefactor in the denominator.

We now consider specific values of q; recall that the angle separating the holes is  $\theta = 2\pi r/q$ . Thus q = 1 is a

q	$\tilde{P}(s)(q/2\pi)^{s+1}$
1	$\frac{\zeta(s)-1}{2s(s+1)(s+2)\zeta(s+1)}$
2	$\frac{\zeta(s)}{s(s+1)(s+2)\zeta(s+1)}$
3	$\frac{3^{s}(7\zeta(s)+2^{s+2}(\zeta(s)-1)+2)-\zeta(s)(2^{s+2}+1)}{2s(s+1)(s+2)(3^{s+1}-1)\zeta(s+1)}$
4	$\frac{2^{s}(13\zeta(s)+3^{s+2}(\zeta(s)-1)+3)-\zeta(s)(3^{s+2}+5)}{4s(s+1)(s+2)(2^{s+1}-1)\zeta(s+1)}$
6	$[(\pi/3)^{s+1}(6^s+8.12^s-25.30^s+(1-3.2^s-13.3^s-8.4^s +25.5^s+27.6^s-25.10^s+8.12^s-25.15^s+25.30^s)\zeta(s))]$
	$\times [2s(s+1)(s+2)(2^{s+1}-1)(3^{s+1}-1)\zeta(s+1)]^{-1}$

TABLE I: The function  $\tilde{P}(s)(q/2\pi)^{s+1}$  (see Eq. 14) for q=1, 2, 3, 4, 6 and r = 1.

q		s		
	1	-1	-2	-3
1	2	$-\frac{13}{12}$	$\frac{3}{2\pi}$	$\frac{119}{5760\pi^2\zeta'(-2)}$
2	1	$-\frac{1}{6}$	0	$-\frac{1}{720\pi^2\zeta'(-2)}$
3	1	$-\frac{1}{4} - \frac{5 \ln 2}{9 \ln 3}$	$\frac{3}{4\pi}$	$\frac{49}{5120\pi^2\zeta'(-2)}$
4	1	$-\frac{1}{3} - \frac{11 \ln 3}{16 \ln 2}$	$\frac{3}{\pi}$	$\frac{109}{1620\pi^2\zeta'(-2)}$
6	1	$\begin{aligned} [5 \ln 5 (10 \ln 3 - 7 \ln 5) + & \ln 2 (55 \ln 5 - 76 \ln 3) \\ + & (10 \ln 5 - 8 \ln 2) (7 \ln \epsilon + 12 \zeta'(-1))] \\ \times & [72 \ln 2 \ln 3]^{-1} \end{aligned}$	$-\frac{3}{2\pi}$	$-\frac{79}{6400\pi^2\zeta'(-2)}$

TABLE II: Some residues of  $\tilde{P}(s)\epsilon^{-s}$  given in table I divided by the factor  $e^{-s}$ . The  $\ln e$  appears for q=6 due to a double pole at s = -1. There are also poles for further negative odd s, and along the critical line  $\Re s = -1/2$ .

single hole and q=2 is two opposite holes. Experimentalists could especially notice a contrast between small values of q in which the angles are simple rational multiples of  $\pi$  and the escape rate is expressed in terms of only a few L-functions (in fact only the Riemann zeta function for q = 1, 2, 3, 4, 6, and angles which are not close to rational numbers with small denominators. Particular values of P(s) are given in table I and residues of the trivial poles at integer s are given in table II. Some points to note are that the leading behavior at s = 1, that is, of order  $e^{-1}$  is purely given by the total size of the holes. The q = 1 case is twice as large since there is only a single hole in this case. The next possible term would be s=0, however the residue is zero since the  $\zeta(s+1)$ in the denominator has a pole there. The s=-1 term is more complicated for q=6, involving a term in  $\epsilon \ln \epsilon$ due to the double pole in this case. The s=-2 terms are remarkably simple, and are due to the s+2 in the denominator. For these values of q the second to leading order terms, which are not given in the table, come from the nontrivial zeroes of the  $\zeta(s+1)$ , and for multiplicity m are of order  $\sqrt{\epsilon}(\ln \epsilon)^{m-1}$  if all zeroes of  $\zeta(s)$  lie in  $\Re s < 1/2$ . The latter is a statement of the Riemann hypothesis [22]. An alternative formulation stating that all the nontrivial zeroes of  $\zeta(s)$  have  $\Re s = 1/2$  is easily

shown to be equivalent using the functional equation [22] relating  $\zeta(s)$  and  $\zeta(1-s)$ . Thus this celebrated unsolved problem is equivalent to either of

$$\lim_{\epsilon \to 0} \lim_{t \to \infty} \epsilon^{\delta - 1/2} (tP_1(t) - 2/\epsilon) = 0 \qquad (15)$$

$$\lim_{\epsilon \to 0} \lim_{t \to \infty} \epsilon^{\delta - 1/2} (t P_1(t) - 2/\epsilon) = 0 \qquad (15)$$

$$\lim_{\epsilon \to 0} \lim_{t \to \infty} \epsilon^{\delta - 1/2} (t P_1(t) - 2t P_2(t)) = 0 \qquad (16)$$

for every  $\delta > 0$ , and the subscript indicates the one or symmetric two hole problem. This is our second main result: The difference between the escape of the one and two hole problems is determined to leading order in the small hole limit by the Riemann Hypothesis. The generalised Riemann hypothesis is the equivalent statement for L functions, and implies that corrections are of order  $e^{\delta+1/2}$  in the rational two hole case. For irrational  $\theta$  the above analysis breaks down; presumably the poles on the critical line become dense, blocking analytic continuation. However the leading order (in  $\epsilon$ ) term can be shown to be  $\theta$  independent for  $\theta > 0$ , as for the rational values given above, as follows. For the leading order behavior, the sum over n can be approximated by an integral, with parts of the summand replaced by "mean field" averages  $\langle \rangle$ . If  $\theta$  is irrational, the fractional parts are uniformly distributed, so that we compute

$$\langle g\left(\frac{2\pi}{n} - \theta' - \epsilon\right) + g\left(\theta' - \epsilon\right) \rangle$$

$$= \frac{n}{2\pi} \int_0^{2\pi/n} \left[ g\left(\frac{2\pi}{n} - \theta' - \epsilon\right) + g\left(\theta' - \epsilon\right) \right] d\theta'$$

$$= \frac{n}{3\pi} \left(\frac{2\pi}{n} - \epsilon\right)^3$$
(17)

We also use  $\langle \phi(n) \rangle = 6n/\pi^2$  and  $\langle \mu(n) \rangle = 0$ , so that

$$tP(t) \approx \frac{1}{24\pi^2} \int_0^{2\pi/\epsilon} n^2 \frac{6n}{\pi^2} \left(\frac{2\pi}{n} - \epsilon\right)^3 dn = \frac{1}{\epsilon}$$
 (18)

as required.

We now present some numerical tests. The main results of this paper are exact. However there are some related questions to do with rates of convergence of various limits which are of great importance to numerical or experimental extensions of this work. The rate of convergence of tP(t) as  $t\to\infty$  is considered in Fig. 3. The convergence of Eq.(14) with the number of residues is tested in Fig. 4. Note that considering only the real poles would lead to a Taylor series of integer powers, that is, an analytic function; the complex poles are essential to obtain the step structure.

In conclusion, we computed the escape from a circular billiard with one hole and related it to the Riemann Hypothesis, computed escape for two holes (rational case) and related it to the generalized Riemann hypotheses and obtained the leading order behavior for the irrational two hole case. Many interesting questions remain, concerning

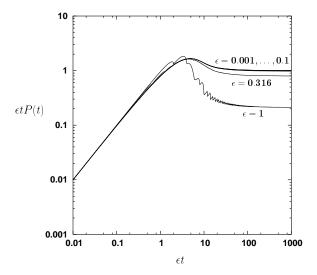

FIG. 3: The scaled survival probability  $\epsilon t P(t)$  (see Eq. 4) appears to approach a limiting function as  $\epsilon \to 0$  with  $\epsilon t$  held constant. Here we use  $10^8$  random initial conditions,  $\theta = 1$  (an irrational multiple of  $\pi$ ) and the curves are  $\epsilon = 10^{-n/2}$  with  $n = 0 \dots 6$ . At large  $\epsilon t$  the function converges to unity, consistent with Eq. (18).

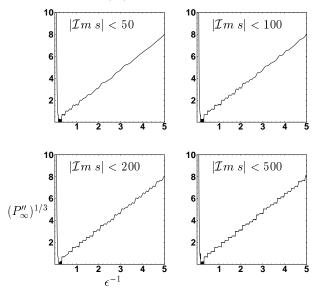

FIG. 4: Numerical computation of  $P''_{\infty}(\epsilon)$  for the single hole case q=1, using Eq. (14) and varying the number of poles considered on the critical line; real poles are considered for s>-10 in all plots. From (4) it is seen that the second derivative of  $P_{\infty}$  is a function with uniformly spaced steps and constant average gradient in the variables shown on the axes. Convergence is evident except for very small  $\epsilon^{-1}$  for which more real poles would be required; large  $\epsilon^{-1}$  require more critical poles for the steps to be visible.

one or two hole escape from pseudo-integrable, chaotic or mixed billiards, and to the quantum/wave signature of these systems [23]. A fuller understanding of open quantum billiards should have important practical benefits, for example in the design of microlasers [24].

We would like to thank E. Croot and Z. Rudnick for helpful discussions. LB was partially supported by NSF grant DMS #0140165. CD is grateful for the hospitality of the Center for Nonlinear Science, Georgia Tech.
